Abstract

This paper overviews recent work on ant algorithms, that is, algorithms for discrete optimization which took inspiration from the observation of ant colonies foraging behavior, and introduces the ant colony optimization (ACO) meta-heuristic. In the first part of the paper the basic biological findings on real ants are overviewed, and their artificial counterparts as well as the ACO meta-heuristic are defined. In the second part of the paper a number of applications to combinatorial optimization and routing in communications networks are described. We conclude with a discussion of related work and of some of the most important aspects of the ACO meta-heuristic.

1 Introduction

Ant algorithms were first proposed by Dorigo and colleagues [33, 39] as a multi-agent approach to difficult combinatorial optimization problems like the traveling salesman problem (TSP) and the quadratic assignment problem (QAP). There is currently a lot of ongoing activity in the scientific community to extend/apply ant-based algorithms to many different discrete optimization problems [5, 21]. Recent applications cover problems like vehicle routing, sequential ordering, graph coloring, routing in communications networks, and so on.

Ant algorithms were inspired by the observation of real ant colonies. Ants are social insects, that is, insects that live in colonies and whose behavior is directed more to the survival of the colony as a whole than to that of a single individual component of the colony. Social insects have captured the attention of many scientists because of the high structuration level their colonies can achieve, especially when compared to the relative simplicity of the colony's individuals. An important and interesting behavior of ant colonies is their foraging behavior, and, in particular, how ants can find shortest paths between food sources and their nest.

While walking from food sources to the nest and vice versa, ants deposit on the ground a substance called *pheromone*, forming in this way a pheromone trail. Ants can smell pheromone and, when choosing their way, they tend to choose, in probability, paths marked by strong pheromone concentrations. The pheromone trail allows the ants to find their

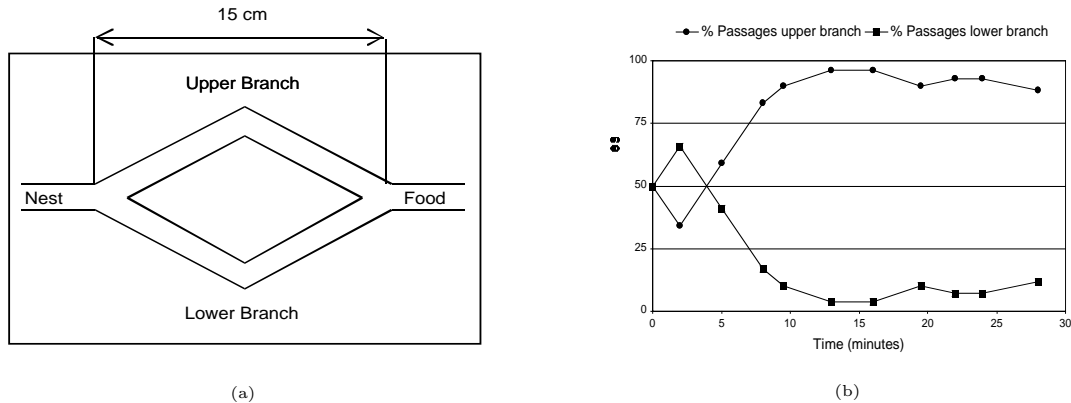

Figure 1. Single bridge experiment. (a) Experimental setup. (b) Results for a typical single trial, showing the percentage of passages on each of the two branches per unit of time as a function of time. Eventually, after an initial short transitory phase, the upper branch becomes the most used. After Deneubourg et al., 1990 [25].

way back to the food source (or to the nest). Also, it can be used by other ants to find the location of the food sources found by their nestmates.

It has been shown experimentally that this pheromone trail following behavior can give rise, once employed by a colony of ants, to the emergence of shortest paths. That is, when more paths are available from the nest to a food source, a colony of ants may be able to exploit the pheromone trails left by the individual ants to discover the shortest path from the nest to the food source and back.

In order to study in controlled conditions the ants' foraging behavior, the binary bridge experiment has been set up by Deneubourg et al. [25] (see Figure 1a). The nest of a colony of ants of the species *Linepithema humile* and a food source have been separated by a double bridge in which each branch has the same length. Ants are then left free to move between the nest and the food source and the percentage of ants which choose one or the other of the two branches is observed over time. The result (see Figure 1b) is that after an initial transitory phase in which some oscillations can appear, ants tend to converge on a same path.

In the above experiment initially there is no pheromone on the two branches, which are therefore selected by the ants with the same probability. Nevertheless, random fluctuations, after an initial transitory phase, cause a few more ants to randomly select one branch, the upper one in the experiment shown in Figure 1a, over the other. Because ants deposit pheromone while walking, the greater number of ants on the upper branch determines a greater amount of pheromone on it, which in turn stimulates more ants to choose it, and so on. The probabilistic model that describes this phenomenon, which closely matches the experimental observations, is the following [58]. We first make the assumption that the amount of pheromone on a branch is proportional to the number of ants that used the branch in the past. This assumption implies that pheromone evaporation is not taken into account. Given that an experiment typically lasts approximately one hour, it is plausible to assume that the amount of pheromone evaporated in this time period is negligible. In the model, the probability of choosing a branch at a certain time depends on the total amount of pheromone on the branch, which in turn is proportional to the number of ants that used the branch until that time. More precisely, let U_m and L_m be the numbers of ants that have used the upper and lower branch after m ants have crossed the bridge, with $U_m + L_m = m$. The probability $P_U(m)$ with which the $(m+1)$ -th ant chooses the upper branch is

$$P_U(m) = \frac{(U_m + k)^h}{(U_m + k)^h + (L_m + k)^h} \quad (1)$$

while the probability $P_L(m)$ that it chooses the lower branch is $P_L(m) = 1 - P_U(m)$. This

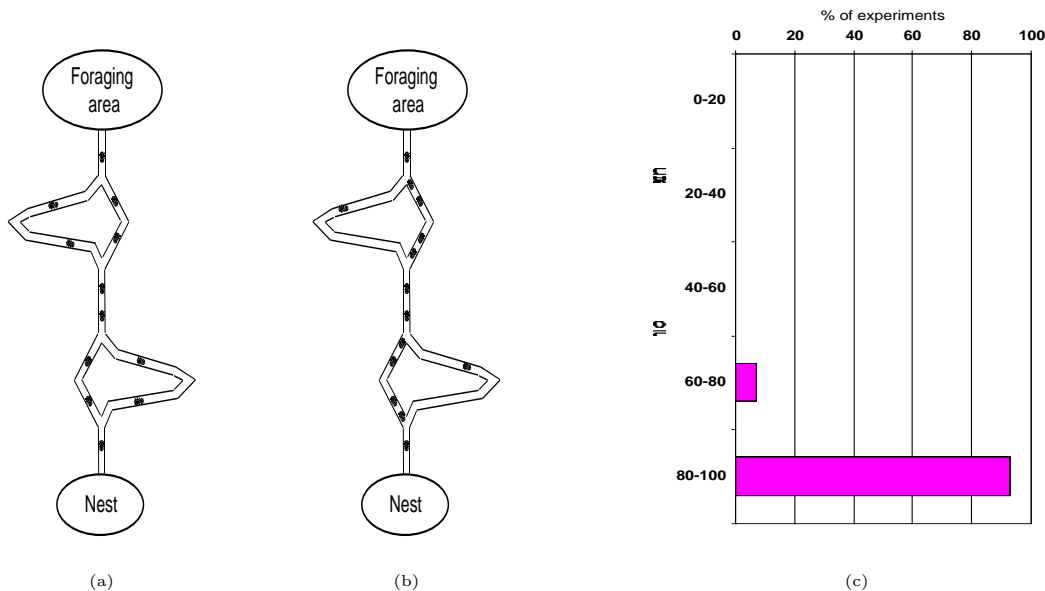

Figure 2. Double bridge experiment. (a) Ants start exploring the double bridge. (b) Eventually most of the ants choose the shortest path. (c) Distribution of the percentage of ants that selected the shorter path. After Goss et al. 1989 [58].

functional form of the probability of choosing a branch over the other was obtained from experiments on trail-following [80]; the parameters h and k allow to fit the model to experimental data. The ant choice dynamics follows from the above equation: $U_{m+1} = U_m + 1$, if $\psi \leq P_U$, $U_{m+1} = U_m$ otherwise, where ψ is a random variable uniformly distributed over the interval $[0,1]$.

Monte Carlo simulations were run to test the correspondence between this model and the real data: results of simulations were in agreement with the experiments with real ants when parameters were set to $k \approx 20$ and $h \approx 2$ [80].

It is easy to modify the experiment above to the case in which the bridge’s branches are of different length [58], and to extend the model of Equation 1 so that it can describe this new situation. In this case, because of the same pheromone laying mechanism as in the previous situation, the shortest branch is most often selected: The first ants to arrive at the food source are those that took the two shortest branches, so that, when these ants start their return trip, more pheromone is present on the short branch than on the long branch, stimulating successive ants to choose the short branch. In this case, the importance of initial random fluctuations is much reduced, and the stochastic pheromone trail following behavior of the ants coupled to differential branch length is the main mechanism at work. In Figure 2 are shown the experimental apparatus and the typical result of an experiment with a double bridge with branches of different lengths.

It is clear that what is going on in the above described process is a kind of distributed optimization mechanism to which each single ant gives only a very small contribution. It is interesting that, although a single ant is in principle capable of building a solution (i.e., of finding a path between nest and food reservoir), it is only the ensemble of ants, that is the ant colony, which presents the “shortest path finding” behavior.¹ In a sense, this behavior is an emergent property of the ant colony. It is also interesting to note that ants can perform this specific behavior using a simple form of indirect communication mediated by pheromone laying, known as *stigmergy* [60].

As defined by Grassé in his work on *Bellicositermes Natalensis* and *Cubitermes* [60], stigmergy is the “stimulation of workers² by the performance they have achieved.”

¹ The above described experiments have been run in strongly constrained conditions. A formal proof of the pheromone driven shortest path finding behavior in the general case is missing. Bruckstein et al. [9, 10] consider the shortest path finding problem in absence of obstacles for ants driven by visual clues and not by pheromones, and prove the convergence of the ants path to the straight line.

² Workers are one of the castes in termite colonies. Although Grassé introduced the term stigmergy to

In fact, Grassé (1946) [59] observed that insects are capable to respond to so called “significant stimuli” which activate a genetically encoded reaction. In social insects, of which termites and ants are some of the best known examples, the effects of these reactions can act as new significant stimuli for both the insect that produced them and for other insects in the colony. The production of a new significant stimulus as a consequence of the reaction to a significant stimulus determines a form of coordination of the activities and can be interpreted as a form of indirect communication. For example, Grassé [60] observed that *Bellicositermes Natalensis* as well as *Cubitermes*, when building a new nest, start by a random, non coordinated activity of earth-pellet depositing. But once the earth-pellet reach a certain density in a restricted area they become a new significant stimulus which causes more termites to add earth-pellet so that pillar and arches, and eventually the whole nest, are built.

What characterizes stigmergy from other means of communication is (i) the physical nature of the information released by the communicating insects, which corresponds to a modification of physical environmental states visited by the insects, and (ii) the local nature of the released information, which can only be accessed by insects that visit the state in which it was released (or some neighborhood of that state).

Accordingly, in this paper we take the stance that it is possible to talk of stigmergetic communication whenever there is an “indirect communication mediated by physical modifications of environmental states which are only locally accessible by the communicating agents.”

One of the main tenet of this paper is that the stigmergetic model of communication in general, and the one inspired by ants foraging behavior in particular, is an interesting model for artificial multi-agent systems applied to the solution of difficult optimization problems. In fact, the above-mentioned characteristics of stigmergy can easily be extended to artificial agents by (i) associating to problem states appropriate state variables, and (ii) by giving the artificial agents only local access to these variables’ values.

For example, in the above described foraging behavior of ants, stigmergetic communication is at work via the pheromone that ants deposit on the ground while walking. Correspondingly, our artificial ants will simulate pheromone laying by modifying appropriate “pheromone variables” associated to problem states they visit while building solutions to the optimization problem to which they are applied. Also, according to the stigmergetic communication model, our artificial ants will have only local access to these pheromone variables.

Another important aspect of real ants’ foraging behavior that is exploited by artificial ants is the coupling between the *autocatalytic (positive feedback)* mechanism [39] and the *implicit evaluation* of solutions. By implicit solution evaluation we mean the fact that shorter paths (which correspond to lower cost solutions in artificial ants) will be completed earlier than longer ones, and therefore they will receive pheromone reinforcement more quickly. Implicit solution evaluation coupled with autocatalysis can be very effective: the shorter the path, the sooner the pheromone is deposited by the ants, the more the ants that use the shorter path. If appropriately used, autocatalysis can be a powerful mechanism in population-based optimization algorithms (e.g., in evolutionary computation algorithms [44, 64, 82, 88] autocatalysis is implemented by the selection/reproduction mechanism). In fact, it quickly favors the best individuals, so that they can direct the search process. When using autocatalysis some care must be taken to avoid premature convergence (*stagnation*), that is, the situation in which some not very good individual takes over the population just because of a contingent situation (e.g., because of a local optimum, or just because of initial random fluctuations which caused a not very good individual to be much better than all the other individuals in the population) impeding further exploration of the search space. We will see that pheromone trail evaporation and stochastic state transitions are

explain the behavior of termite societies, the same term has been used to describe indirect communication mediated by modifications of the environment that can be observed also in other social insects.

the needed complements to autocatalysis drawbacks.

In the following of this paper we discuss a number of ant algorithms based on the above ideas. We start by defining, in Section 2, the characterizing aspects of ant algorithms and the Ant Colony Optimization (ACO) meta-heuristic.³ Section 3 overviews most of the applications of ACO algorithms. In Section 4 we briefly discuss related work, and in Section 5 we discuss some of the characteristics of implemented ACO algorithms. Finally, we draw some conclusions in Section 6.

2 The ant colony optimization approach

In the ant colony optimization (ACO) meta-heuristic a colony of artificial ants cooperate in finding good solutions to difficult discrete optimization problems. Cooperation is a key design component of ACO algorithms: The choice is to allocate the computational resources to a set of relatively simple agents (artificial ants) that communicate indirectly by stigmergy. Good solutions are an emergent property of the agents' cooperative interaction.

Artificial ants have a double nature. On the one hand, they are an abstraction of those behavioral traits of real ants which seemed to be at the heart of the shortest path finding behavior observed in real ant colonies. On the other hand, they have been enriched with some capabilities which do not find a natural counterpart. In fact, we want ant colony optimization to be an engineering approach to the design and implementation of software systems for the solution of difficult optimization problems. It is therefore reasonable to give artificial ants some capabilities that, although not corresponding to any capacity of their real ants counterparts, make them more effective and efficient. In the following we discuss first the nature inspired characteristics of artificial ants, and then how they differ from real ants.

2.1 Similarities and differences with real ants

Most of the ideas of ACO stem from real ants. In particular, the use of: (i) a colony of cooperating individuals, (ii) an (artificial) pheromone trail for local stigmergetic communication, (iii) a sequence of local moves to find shortest paths, and (iv) a stochastic decision policy using local information and no lookahead.

Colony of cooperating individuals. As real ant colonies, ant algorithms are composed of a population, or colony, of concurrent and asynchronous entities globally cooperating to find a good “solution” to the task under consideration. Although the complexity of each artificial ant is such that it can build a feasible solution (as a real ant can find somehow a path between the nest and the food), high quality solutions are the result of the cooperation among the individuals of the whole colony. Ants cooperate by means of the information they concurrently read/write on the problem's states they visit, as explained in the next item.

Pheromone trail and stigmergy. Artificial ants modify some aspects of their environment as the real ants do. While real ants deposit on the world's state they visit a chemical substance, the pheromone, artificial ants change some numeric information locally stored in the problem's state they visit. This information takes into account the ant's current history/performance and can be read/written by any ant accessing

³ It is important here to clarify briefly the terminology used. We talk of ACO meta-heuristic to refer to the general procedure presented in Section 2. The term ACO algorithm will be used to indicate any generic instantiation of the ACO meta-heuristic. Alternatively, we will also talk more informally of ant algorithms to indicate any algorithm that, while following the general guidelines set above, not necessarily follows all the aspects of the ACO meta-heuristic. Therefore, all ACO algorithms are also ant algorithms, though the vice versa is not true (e.g., we will see that HAS-QAP is an ant, but not strictly an ACO algorithm).

the state. By analogy, we call this numeric information *artificial pheromone trail*, pheromone trail for short in the following. In ACO algorithms local pheromone trails are the only communication channels among the ants. This stigmergetic form of communication plays a major role in the utilization of collective knowledge. Its main effect is to change the way the environment (the problem landscape) is locally perceived by the ants as a function of all the past history of the whole ant colony. Usually, in ACO algorithms an evaporation mechanism, similar to real pheromone evaporation, modifies pheromone information over time. Pheromone evaporation allows the ant colony to slowly forget its past history so that it can direct its search towards new directions without being over-constrained by past decisions.

Shortest path searching and local moves. Artificial and real ants share a common task: to find a shortest (minimum cost) path joining an origin (nest) to destination (food) sites. Real ants do not jump, they just walk through adjacent terrain’s states, and so do artificial ants, moving step-by-step through “adjacent states” of the problem. Of course, exact definitions of state and adjacency are problem-specific.

Stochastic and myopic state transition policy. Artificial ants, as real ones, build solutions applying a probabilistic decision policy to move through adjacent states. As for real ants, the artificial ants’ policy makes use of local information only and it does not make use of lookahead to predict future states. Therefore, the applied policy is completely local, in space and time. The policy is a function of both the a priori information represented by the problem specifications (equivalent to the terrain’s structure for real ants), and of the local modifications in the environment (pheromone trails) induced by past ants.

As we said, artificial ants have also some characteristics which do not find their counterpart in real ants.

- Artificial ants live in a *discrete world* and their moves consist of transitions from discrete states to discrete states.
- Artificial ants have an *internal state*. This private state contains the memory of the ant past actions.
- Artificial ants deposit an amount of pheromone which is a function of the *quality of the solution* found.⁴
- Artificial ants timing in pheromone laying is problem dependent and often does not reflect real ants behavior. For example, in many cases artificial ants update pheromone trails only after having generated a solution.
- To improve overall system efficiency, ACO algorithms can be enriched with *extra capabilities* like lookahead, local optimization, backtracking, and so on, that cannot be found in real ants. In many implementations ants have been hybridized with local optimization procedures (see for example [37, 50, 92]), while, so far, only Michel and Middendorf [76] have used a simple one-step lookahead function and there are no examples of backtracking procedures added to the basic ant capabilities, except for simple recovery procedures used by Di Caro and Dorigo [26, 28].⁵

In the following section we will show how artificial ants can be put to work in an algorithmic framework so that they can be applied to discrete optimization problems.

⁴ In reality, some real ants have a similar behavior: they deposit more pheromone in case of richer food sources.

⁵ Usually, backtracking strategies are suitable to solve constraint satisfaction problems, (e.g., n -queens) and lookahead is very useful when the cost of making a local prediction about the effect of future moves is much lower than the cost of the real execution of the move sequence (e.g., mobile robotics). To our knowledge, until now ACO algorithms have not been applied to these classes of problems.

2.2 The ACO meta-heuristic

In ACO algorithms a finite size colony of artificial ants with the above described characteristics collectively searches for good quality solutions to the optimization problem under consideration. Each ant builds a solution, or a component of it⁶, starting from an initial state selected according to some problem dependent criteria. While building its own solution, each ant collects information on the problem characteristics and on its own performance, and uses this information to modify the representation of the problem, as seen by the other ants. Ants can act concurrently and independently, showing a cooperative behavior. They do not use direct communication: it is the stigmergy paradigm that governs the information exchange among the ants.

An incremental constructive approach is used by the ants to search for a feasible solution.

A solution is expressed as a minimum cost (shortest) path through the states of the problem in accordance with the problem's constraints. The complexity of each ant is such that even a single ant is able to find a (probably poor quality) solution. High quality solutions are only found as the emergent result of the global cooperation among all the agents of the colony concurrently building different solutions.

According to the assigned notion of neighborhood (problem-dependent), each ant builds a solution by moving through a (finite) sequence of neighbor states. Moves are selected by applying a stochastic local search policy directed (i) by ant private information (the ant internal state, or memory) and (ii) by publicly available pheromone trail and a priori problem-specific local information.

The ant's internal state stores information about the ant past history. It can be used to carry useful information to compute the value/goodness of the generated solution and/or the contribution of each executed move. Moreover it can play a fundamental role to manage the feasibility of the solutions. In some problems in fact, typically in combinatorial optimization, some of the moves available to an ant in a state can take the ant to an infeasible state. This can be avoided exploiting the ant's memory. Ants therefore can build feasible solutions using only knowledge about the local state and about the effects of actions that can be performed in the local state.

The local, public information comprises both some problem-specific heuristic information, and the knowledge, coded in the pheromone trails, accumulated by all the ants from the beginning of the search process. This time-global pheromone knowledge built-up by the ants is a shared local long-term memory that influences the ants' decisions. The decisions about when the ants should release pheromone on the "environment" and how much pheromone should be deposited depend on the characteristics of the problem and on the design of the implementation. Ants can release pheromone while building the solution (online step-by-step), or after a solution has been built, moving back to all the visited states (online delayed), or both. As we said, autocatalysis plays an important role in ACO algorithms functioning: the more ants choose a move, the more the move is rewarded (by adding pheromone) and the more interesting it becomes for the next ants. In general, the amount of pheromone deposited is made proportional to the goodness of the solution an ant has built (or is building). In this way, if a move contributed to generate a high-quality solution its goodness will be increased proportionally to its contribution.

A functional composition of the locally available pheromone and heuristic values defines *ant-decision tables*, that is, probabilistic tables used by the ants' decision policy to direct their search towards the most interesting regions of the search space. The stochastic component of the move choice decision policy and the previously discussed pheromone

⁶ To make more intuitive what we mean by component of a solution, we can consider, as an example, a transportation routing problem: given a set of n cities, $\{c_i\}, i \in \{1, \dots, n\}$, and a network of interconnection roads, we want to find all the shortest paths s_{ij} connecting each city pair $c_i c_j$. In this case, a complete solution is represented by the set of all the $n(n-1)$ shortest path pairs, while a component of a solution is a single path s_{ij} .

evaporation mechanism avoid a rapid drift of all the ants towards the same part of the search space. Of course, the level of stochasticity in the policy and the strength of the updates in the pheromone trail determine the balance between the exploration of new points in the state space and the exploitation of accumulated knowledge. If necessary and feasible, the ants' decision policy can be enriched with problem-specific components like backtracking procedures or lookahead.

Once an ant has accomplished its task, consisting of building a solution and depositing pheromone information, the ant “dies”, that is, it is deleted from the system.

The overall ACO meta-heuristic, beside the two above-described components acting from a local perspective (that is, ants generation and activity, and pheromone evaporation), can also comprise some extra components which use global information and that go under the name of `daemon_actions` in the algorithm reported in Figure 3. For example, a *daemon* can be allowed to observe the ants' behavior, and to collect useful global information to deposit additional pheromone information, biasing, in this way, the ant search process from a non-local perspective. Or, it could, on the basis of the observation of all the solutions generated by the ants, apply problem-specific local optimization procedures and deposit additional pheromone “offline” with respect to the pheromone the ants deposited online.

The three main activities of an ACO algorithm (ants generation and activity, pheromone evaporation, and daemon actions) may need some kind of synchronization, performed by the `schedule_activities` construct of Figure 3. In general, a strictly sequential scheduling of the activities is particularly suitable for non-distributed problems, where the global knowledge is easily accessible at any instant and the operations can be conveniently synchronized. On the contrary, some form of parallelism can be easily and efficiently exploited in distributed problems like routing in telecommunications networks, as will be discussed in Section 3.2.

In Figure 3, a high-level description of the ACO meta-heuristic is reported in pseudo-code. As pointed out above, some described components and behaviors are optional, like daemon activities, or strictly implementation-dependent, like when and how the pheromone is deposited. In general, the online step-by-step pheromone update and the online delayed pheromone update components (respectively, lines 24-27 and 30-34 in the `new_active_ant()` procedure) are mutually exclusive and only in few cases they are both present or both absent (in the case they are absent the pheromone is deposited by the daemon).

ACO algorithms, as a consequence of their concurrent and adaptive nature, are particularly suitable for distributed stochastic problems where the presence of exogenous sources determines a non-stationarity in the problem representation (in terms of costs and/or environment). For example, many problems related to communications or transportation networks are intrinsically distributed and non-stationary and it is often not possible to have an exact model of the underlying variability. On the contrary, because stigmergy is both the only inter-ant communication method and it is spatially localized, ACO algorithms could perform not at best in case of problems where each state has a big-sized neighborhood. In fact, an ant that visits a state with a big-sized neighborhood has a huge number of possible moves among which to choose. Therefore, the probability that many ants visit the same state is very small, and consequently there is little, if any, difference between using or not pheromone trails.

3 Applications of ACO algorithms

There are now available numerous successful implementations of the ACO meta-heuristic (Figure 3) applied to a number of different combinatorial optimization problems. Looking at these implementations it is possible to distinguish among two classes of applications: those to static combinatorial optimization problems, and those to dynamic ones.

```

1 procedure ACO_Meta_heuristic()
2   while (termination_criterion_not_satisfied)
3     schedule_activities
4       ants_generation_and_activity();
5       pheromone_evaporation();
6       daemon_actions(); {optional}
7     end schedule_activities
8   end while
9 end procedure

10 procedure ants_generation_and_activity()
11   while (available_resources)
12     schedule_the_creation_of_a_new_ant();
13     new_active_ant();
14   end while
15 end procedure

16 procedure new_active_ant() {ant lifecycle}
17   initialize_ant();
18    $\mathcal{M}$  = update_ant_memory();
19   while (current_state  $\neq$  target_state)
20      $\mathcal{A}$  = read_local_ant_routing_table();
21      $\mathcal{P}$  = compute_transition_probabilities( $\mathcal{A}$ ,  $\mathcal{M}$ , problem_constraints);
22     next_state = apply_ant_decision_policy( $\mathcal{P}$ , problem_constraints);
23     move_to_next_state(next_state);
24     if (online_step-by-step_pheromone_update)
25       deposit_pheromone_on_the_visited_arc();
26       update_ant_routing_table();
27     end if
28      $\mathcal{M}$  = update_internal_state();
29   end while
30   if (online_delayed_pheromone_update)
31     evaluate_solution();
32     deposit_pheromone_on_all_visited_arcs();
33     update_ant_routing_table();
34   end if
35   die();
36 end procedure

```

Figure 3. The ACO meta-heuristic in pseudo-code. Comments are enclosed in braces. All the procedures at the first level of indentation in the statement `in_parallel` are executed concurrently. The procedure `daemon_actions()` at line 6 is optional and refers to centralized actions executed by a daemon possessing global knowledge. The `target_state` (line 19) refers to a complete solution built by the ant. The step-by-step and delayed pheromone updating procedures at lines 24–27 and 30–34 are often mutually exclusive. When both of them are absent the pheromone is deposited by the daemon.

Static problems are those in which the characteristics of the problem are given once and for all when the problem is defined, and do not change while the problem is being solved. A paradigmatic example of such problems is the classic traveling salesman problem [65, 69, 83], in which city locations and their relative distances are part of the problem definition and do not change at run-time. On the contrary, dynamic problems are defined as a function of some quantities whose value is set by the dynamics of an underlying system. The problem changes therefore at run-time and the optimization algorithm must be capable of adapting online to the changing environment. The paradigmatic example discussed in the following of this section is network routing.

Topological modifications (e.g., adding or removing a node), which are not considered by the above classification, can be seen as transitions between problems belonging to the same class.

Tables 1 and 2 list the available implementations of ACO algorithms. The main characteristics of the listed algorithms are discussed in the following two subsections. We then conclude with a brief review of existing parallel implementations of ACO algorithms.

3.1 Applications of ACO algorithms to static combinatorial optimization problems

The application of the ACO meta-heuristic to a static combinatorial optimization problem is relatively straightforward, once defined a mapping of the problem which allows the incremental construction of a solution, a neighborhood structure, and a stochastic state transition rule to be locally used to direct the constructive procedure.

A strictly implementation dependent aspect of the ACO meta-heuristic regards the timing of pheromone updates (lines 24-27 and 30-34 of the algorithm in Figure 3). In ACO algorithms for static combinatorial optimization the way ants update pheromone trails

changes across algorithms: Any combination of online step-by-step pheromone updates and online delayed pheromone updates is possible.

Another important implementation dependent aspect concerns the `daemon_actions()` component of the ACO meta-heuristic (line 6 of the algorithm in Figure 3). Daemon actions implement actions which require some kind of global knowledge about the problem. Examples are offline pheromone updates and local optimization of solutions built by ants.

Most of the ACO algorithms presented in this subsection are strongly inspired by Ant System (AS), the first work on ant colony optimization [33, 39]. Many of the successive applications of the original idea are relatively straightforward applications of AS to the specific problem under consideration. We start therefore the description of ACO algorithms with AS. Following AS, for each ACO algorithm listed in Table 1 we give a short description of the algorithm’s main characteristics and of the results obtained.

3.1.1 Traveling salesman problem

The first application of an ant colony optimization algorithm was done using the traveling salesman problem (TSP) as a test problem. The main reasons why the TSP, one of the most studied *NP*-hard [69, 83] problems in combinatorial optimization, was chosen are that it is a shortest path problem to which the ant colony metaphor is easily adapted and that it is a didactic problem (that is, it is very easy to understand and explanations of the algorithm behavior are not obscured by too many technicalities).

A general definition of the traveling salesman problem is the following. Consider a set N of nodes, representing cities, and a set E of arcs fully connecting the nodes N . Let d_{ij} be the length of the arc $(i, j) \in E$, that is the distance between cities i and j , with $i, j \in N$. The TSP is the problem of finding a minimal length Hamiltonian circuit on the graph $G = (N, E)$, where an Hamiltonian circuit of graph G is a closed tour visiting once and only once all the $n = |N|$ nodes of G , and its length is given by the sum of the lengths of all the arcs of which it is composed.⁷

In the following we will briefly overview the ACO algorithms that have been proposed for the TSP, starting with Ant System.

⁷ Note that distances need not be symmetric: in an asymmetric TSP (ATSP) $d_{ij} \neq d_{ji}$. Also, the graph need not be fully connected. If it is not, it suffices to add the missing arcs giving them a very high length.

3.1.1.1 Ant System (AS)

Ant System (AS) was the first (1991) [33, 39] ACO algorithm. Its importance resides mainly in being the prototype of a number of ant algorithms which have found many interesting and successful applications.

In AS artificial ants build solutions (tours) of the TSP by moving on the problem graph from one city to another. The algorithm executes t_{max} iterations, in the following indexed by t . During each iteration m ants build a tour executing n steps in which a probabilistic decision (state transition) rule is applied. In practice, when in node i the ant chooses the node j to move to, and the arc (i, j) is added to the tour under construction. This step is repeated until the ant has completed its tour.

Three AS algorithms have been defined [19, 33, 39, 40], which differ by the way pheromone trails are updated. These algorithms are called *ant-density*, *ant-quantity*, and *ant-cycle*. In *ant-density* and *ant-quantity* ants deposit pheromone while building a solution,⁸ while in *ant-cycle* ants deposit pheromone after they have built a complete tour.

Preliminary experiments run on a set of benchmark problems [33, 39, 40] have shown that *ant-cycle*'s performance was much better than that of the other two algorithms. Consequently, research on AS was directed towards a better understanding of the characteristics of *ant-cycle*, which is now known as Ant System, while the other two algorithms were abandoned.

As we said, in AS after ants have built their tours, each ant deposits pheromone on pheromone trail variables associated to the visited arcs to make the visited arcs become more desirable for future ants (that is, online delayed pheromone update is at work). Then the ants die. In AS no daemon activities are performed, while the pheromone evaporation procedure, which happens just before ants start to deposit pheromone, is interleaved with the ants activity.

The amount of pheromone trail $\tau_{ij}(t)$ associated to arc (i, j) is intended to represent the learned desirability of choosing city j when in city i (which also corresponds to the desirability that the arc (i, j) belong to the tour built by an ant). The pheromone trail information is changed during problem solution to reflect the experience acquired by ants during problem solving. Ants deposit an amount of pheromone proportional to the quality of the solutions they produced: the shorter the tour generated by an ant, the greater the amount of pheromone it deposits on the arcs which it used to generate the tour. This choice helps to direct search towards good solutions. The main role of pheromone evaporation is to avoid stagnation, that is, the situation in which all ants end up doing the same tour.

The memory (or internal state) of each ant contains the already visited cities and is called *tabu list* (in the following we will continue to use the term tabu list⁹ to indicate the ant's memory). The memory is used to define, for each ant k , the set of cities that an ant located on city i still has to visit. By exploiting the memory therefore an ant k can build feasible solutions by an implicit state-space graph generation (in the TSP this corresponds to visiting a city exactly once). Also, memory allows the ant to cover the same path to deposit online delayed pheromone on the visited arcs.

The ant-decision table $\mathcal{A}_i = [a_j^i(t)]_{|\mathcal{N}_i|}$ of node i is obtained by the composition of the local pheromone trail values with the local heuristic values as follows:

⁸ These two algorithms differ by the amount of pheromone ants deposit at each step: in *ant-density* ants deposit a constant amount of pheromone, while in *ant-quantity* they deposit an amount of pheromone inversely proportional to the length of the chosen arc.

⁹ The term tabu list is used here to indicate a simple memory that contains the set of already visited cities, and has no relation with tabu search [55, 56].

$$a_{ij}(t) = \frac{[\tau_{ij}(t)]^\alpha [\eta_{ij}]^\beta}{\sum_{l \in \mathcal{N}_i} [\tau_{il}(t)]^\alpha [\eta_{il}]^\beta} \quad \forall j \in \mathcal{N}_i \quad (2)$$

where $\tau_{ij}(t)$ is the amount of pheromone trail on arc (i, j) at time t , $\eta_{ij} = 1/d_{ij}$ is the heuristic value of moving from node i to node j , \mathcal{N}_i is the set of neighbors of node i , and α and β are two parameters that control the relative weight of pheromone trail and heuristic value.

The probability with which an ant k chooses to go from city i to city $j \in \mathcal{N}_i^k$ while building its tour at the t -th algorithm iteration is:

$$p_{ij}^k(t) = \frac{a_{ij}(t)}{\sum_{l \in \mathcal{N}_i^k} a_{il}(t)} \quad (3)$$

where $\mathcal{N}_i^k \subseteq \mathcal{N}_i$ is the set of nodes in the neighborhood of node i that ant k has not visited yet (nodes in \mathcal{N}_i^k are selected from those in \mathcal{N}_i by using the ant private memory \mathcal{M}^k).

The role of the parameters α and β is the following. If $\alpha = 0$, the closest cities are more likely to be selected: this corresponds to a classical stochastic greedy algorithm (with multiple starting points since ants are initially randomly distributed on the nodes). If on the contrary $\beta = 0$, only pheromone amplification is at work: this method will lead to the rapid emergence of a stagnation situation with the corresponding generation of tours which, in general, are strongly sub-optimal [40]. A trade-off between heuristic value and trail intensity therefore appears to be necessary.

After all ants have completed their tour, pheromone evaporation on all arcs is triggered, and then each ant k deposits a quantity of pheromone $\Delta\tau_{ij}^k(t)$ on each arc that it has used:

$$\Delta\tau_{ij}^k(t) = \begin{cases} 1/L^k(t) & \text{if } (i, j) \in T^k(t) \\ 0 & \text{if } (i, j) \notin T^k(t) \end{cases} \quad (4)$$

where $T^k(t)$ is the tour done by ant k at iteration t , and $L^k(t)$ is its length. Note that in the symmetric TSP arcs are considered to be bidirectional so that arcs (i, j) and (j, i) are always updated contemporaneously (in fact, they are the same arc). Different is the case of the asymmetric TSP, where arcs have a directionality, and for which the pheromone trail level on the arcs (i, j) and (j, i) can be different. In this case, therefore, when an ant moves from node i to node j only arc (i, j) , and not (j, i) is updated.

It is clear from Equation 4 that the value $\Delta\tau_{ij}^k(t)$ depends on how well the ant has performed: the shorter the tour done, the greater the amount of pheromone deposited.

In practice, the addition of new pheromone by ants and pheromone evaporation are implemented by the following rule applied to all the arcs:

$$\tau_{ij}(t) \leftarrow (1 - \rho)\tau_{ij}(t) + \Delta\tau_{ij}(t) \quad (5)$$

where $\Delta\tau_{ij}(t) = \sum_{k=1}^m \Delta\tau_{ij}^k(t)$, m is the number of ants at each iteration (maintained constant), and $\rho \in (0, 1]$ is the pheromone trail decay coefficient. The initial amount of pheromone $\tau_{ij}(0)$ is set to a same small positive constant value τ_0 on all arcs, and the total number of ants is set to $m = n$, while α , β and ρ are respectively set to 1, 5 and 0.5; these values were experimentally found to be good by Dorigo [33]. Dorigo et al. [39] introduced also *elitist ants*, that is, a daemon action by which the arcs used by the ant that generated the best tour from the beginning of the trial get extra pheromone.

Ant System was compared with other general purpose heuristics on some relatively small TSP problems (these were problems ranging from 30 to 75 cities). The results [39, 40]

were very interesting and disappointing at a time. AS was able to find and improve the best solution found by a genetic algorithm for Oliver30 [101], a 30-city problem, and it had a performance similar or better than that of some general purpose heuristics with which it was compared. Unfortunately, for problems of growing dimensions AS never reached the best known solutions within the allowed 3,000 iterations, although it exhibited quick convergence to good solutions. These encouraging, although not exceptional, results stimulated a number of researchers to further study the ACO approach to optimization. These efforts have resulted in numerous successful applications, listed in the following sections.

3.1.1.2 Others AS-like approaches

Stützle and Hoos (1997) [92, 93] have introduced Max-Min AS (\mathcal{MMAS}), which is the same as AS, but (i) pheromone trails are only updated offline by the daemon (the arcs which were used by the best ant in the current iteration receive additional pheromone), (ii) pheromone trail values are restricted to an interval $[\tau_{min}, \tau_{max}]$, and (iii) trails are initialized to their maximum value τ_{max} .

Putting explicit limits on the trail strength restricts the range of possible values for the probability of choosing a specific arc according to Equation 3. This helps avoiding stagnation, which was one of the reasons why AS performed poorly when an elitist strategy, like allowing only the best ant to update pheromone trails, was used. To avoid stagnation, which may occur in case some pheromone trails are close to τ_{max} while most others are close to τ_{min} , Stützle and Hoos have added what they call a “trail smoothing mechanism”; that is, pheromone trails are updated using a proportional mechanism: $\Delta\tau_{ij} \propto (\tau_{max} - \tau_{ij}(t))$. In this way the relative difference between the trail strengths gets smaller, which obviously favors the exploration of new paths. They found that, when applied to the TSP, \mathcal{MMAS} finds significantly better tours than AS, although comparable to those obtained with ACS (ACS is an extension of AS discussed in Section 3.1.1.3).

Bullnheimer, Hartl and Strauss [12] proposed yet another modification of AS, called AS_{rank} . In AS_{rank} , as it was the case in \mathcal{MMAS} , the only pheromone updates are performed by the daemon, that implements the following activities: (i) the m ants are ranked by tour length $(L_1(t), L_2(t), \dots, L_m(t))$ and the arcs which were visited by one of the first $\sigma - 1$ ants in the ranking receive an amount of pheromone proportional to the visiting ant rank, and (ii) the arcs used by the ant that generated the best tour from beginning of the trial also receive additional pheromone (this is equivalent to AS’s elitist ants pheromone updating). These are both forms of offline pheromone update. In their implementation the contribution of the best tour so far was multiplied by σ . The dynamics of the amount of pheromone $\tau_{ij}(t)$ is given by:

$$\tau_{ij}(t) \leftarrow (1 - \rho)\tau_{ij}(t) + \sigma\Delta\tau_{ij}^+(t) + \Delta\tau_{ij}^r(t) \quad (6)$$

where $\Delta\tau_{ij}^+(t) = 1/L^+(t)$, L^+ being the length of the best solution from beginning of the trial, and $\Delta\tau_{ij}^r(t) = \sum_{\mu=1}^{\sigma-1} \Delta\tau_{ij}^\mu(t)$, with $\Delta\tau_{ij}^\mu(t) = (\sigma - \mu)1/L^\mu(t)$ if the ant with rank μ has used arc (i, j) in its tour and $\Delta\tau_{ij}^\mu(t) = 0$ otherwise. $L^\mu(t)$ is the length of the tour performed by the ant with rank μ at iteration t . Equation 6 is applied to all arcs and implements therefore both pheromone evaporation and offline pheromone updating. They found that this new procedure improves significantly the quality of the results obtained with AS.

3.1.1.3 Ant colony system (ACS), ACS-3-opt, and Ant-Q

The Ant Colony System (ACS) algorithm has been introduced by Dorigo and Gambardella (1996) [36, 37, 49] to improve the performance of AS, that was able to find good solutions within a reasonable time only for small problems. ACS is based on AS but presents some important differences.

First, the daemon updates pheromone trails offline: at the end of an iteration of the algorithm, once all the ants have built a solution, pheromone trail is added to the arcs used by the ant that found the best tour from the beginning of the trial. In ACS-3-opt the daemon first activates a local search procedure based on a variant of the 3-opt local search procedure [71] to improve the solutions generated by the ants and then performs offline pheromone trail update. The offline pheromone trail update rule is:

$$\tau_{ij}(t) \leftarrow (1 - \rho)\tau_{ij}(t) + \rho\Delta\tau_{ij}(t) \quad (7)$$

where $\rho \in (0, 1]$ is a parameter governing pheromone decay, $\Delta\tau_{ij}(t) = 1/L^+$, and L^+ is the length of T^+ , the best tour since the beginning of the trial. Equation 7 is applied only to the arcs (i, j) 's belonging to T^+ .

Second, ants use a different decision rule, called *pseudo-random-proportional* rule, in which an ant k on city i chooses the city $j \in \mathcal{N}_i^k$ to move to as follows. Let $\mathcal{A}_i = [a_{ij}(t)]_{|\mathcal{N}_i|}$ be the ant-decision table:

$$a_{ij}(t) = \frac{[\tau_{ij}(t)][\eta_{ij}]^\beta}{\sum_{l \in \mathcal{N}_i} [\tau_{il}(t)][\eta_{il}]^\beta} \quad \forall j \in \mathcal{N}_i \quad (8)$$

Let q be a random variable uniformly distributed over $[0, 1]$, and $q_0 \in [0, 1]$ be a tunable parameter. The *pseudo-random-proportional* rule, used by ant k located in node i to choose the next node $j \in \mathcal{N}_i^k$, is the following: if $q \leq q_0$ then

$$p_{ij}^k(t) = \begin{cases} 1 & \text{if } j = \arg \max a_{ij} \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

otherwise, when $q > q_0$

$$p_{ij}^k(t) = \frac{a_{ij}(t)}{\sum_{l \in \mathcal{N}_i^k} a_{il}(t)} \quad (10)$$

This decision rule has a double function: when $q \leq q_0$ the decision rule exploits the knowledge available about the problem, that is, the heuristic knowledge about distances between cities and the learned knowledge memorized in the form of pheromone trails, while when $q > q_0$ it operates a biased exploration (equivalent to AS's Equation 3). Tuning q_0 allows to modulate the degree of exploration and to choose whether to concentrate the activity of the system on the best solutions or to explore the search space.

Third, in ACS ants perform only online step-by-step pheromone updates. These updates are performed to favor the emergence of other solutions than the best so far. The pheromone updates are performed by applying the rule:

$$\tau_{ij}(t) \leftarrow (1 - \varphi)\tau_{ij}(t) + \varphi\tau_0 \quad (11)$$

where $0 < \varphi \leq 1$.

Equation 11 says that an ant moving from city i to city $j \in \mathcal{N}_i^k$ updates the pheromone trail on arc (i, j) . The value τ_0 is the same as the initial value of pheromone trails and it was experimentally found that setting $\tau_0 = (nL_{nn})^{-1}$, where n is the number of cities and L_{nn} is the length of a tour produced by the nearest neighbor heuristic [54], produces good results. When an ant moves from city i to city j , the application of the local update rule makes the corresponding pheromone trail τ_{ij} diminish. The rationale for decreasing the pheromone trail on the path an ant is using to build a solution is the following. Consider an ant k_2 starting in city 2 and moving to city 3, 4, and so on, and an ant k_1 starting in city 1 and choosing city 2 as the first city to move to. Then, there are good chances that ant k_1 will follow ant k_2 with one step delay. The trail decreasing effect obtained by applying the local update rule reduces the risk of such a situation. In other words, ACS's local update rule has the effect of making the visited arcs less and less attractive as they are visited by ants, indirectly favoring the exploration of not yet visited arcs. As a consequence, ants tend not to converge to a common path. This fact, which was observed experimentally [37], is a desirable property given that if ants explore different paths then there is a higher probability that one of them will find an improving solution than there is in the case that they all converge to the same tour (which would make the use of m ants pointless).

Last, ACS exploits a data structure called *candidate list* which provides additional local heuristic information. A candidate list is a list of preferred cities to be visited from a given city. In ACS when an ant is in city i , instead of examining all the unvisited neighbors of i , it chooses the city to move to among those in the candidate list; only if no candidate list city has unvisited status then other cities are examined. The candidate list of a city contains cl cities ordered by increasing distance (cl is a parameter), and the list is scanned sequentially and according to the ant tabu list to avoid already visited cities.

ACS was tested (see [36, 37] for detailed results) on standard problems, both symmetric and asymmetric, of various sizes and compared with many other meta-heuristics. In all cases its performance, both in terms of quality of the solutions generated and of CPU time required to generate them, was the best one.

ACS-3-opt performance was compared to that of the genetic algorithm (with local optimization) [46, 47] that won the First International Contest on Evolutionary Optimization [2]. The two algorithms showed similar performance with the genetic algorithm behaving slightly better on symmetric problems and ACS-3-opt on asymmetric ones.

To conclude, we mention that ACS was the direct successor of Ant-Q (1995) [35, 48], an algorithm that tried to merge AS and Q-learning [99] properties. In fact, Ant-Q differs from ACS only in the value τ_0 used by ants to perform online step-by-step pheromone updates. The idea was to update pheromone trails with a value which was a prediction of the value of the next state. In Ant-Q, an ant k implements online step-by-step pheromone updates by the following equation which replaces Equation 11:

$$\tau_{ij}(t) \leftarrow (1 - \varphi)\tau_{ij}(t) + \varphi\gamma \cdot \max_{l \in \mathcal{N}_j^k} \tau_{jl} \quad (12)$$

Unfortunately, it was later found that setting the complicate prediction term to a small constant value, as it is done in ACS, resulted in approximately the same performance. Therefore, although having a good performance, Ant-Q was abandoned for the equally good but simpler ACS.

Also, other versions of ACS were studied which differ from the one described above because of (i) the way online step-by-step pheromone updates was implemented (in [37] experiments were run disabling it, or by setting the update term in Equation 11 to the value $\tau_0 = 0$), (ii) the way the decision rule was implemented (in [48] the *pseudo-random-proportional* rule of Equations 9 and 10 was compared to the *random-proportional* rule of Ant System, and to a *pseudo-random* rule which differs from the *pseudo-random-proportional* rule because random choices are done uniformly random), and (iii) the type

of solution used by the daemon to update the pheromone trails (in [37] the use of the best solution found in the current iteration was compared with ACS's use of the best solution found from the beginning of the trial). ACS as described above is the best performing of all the algorithms obtained by combinations of the above-mentioned choices.

3.1.2 Quadratic assignment problem

The quadratic assignment problem (QAP) is the problem of assigning n facilities to n locations so that the cost of the assignment, which is a function of the way facilities have been assigned to locations, is minimized [67]. The QAP was, after the TSP, the first problem to be attacked by an AS-like algorithm. This was a reasonable choice, since the QAP is a generalization of the TSP.¹⁰ Maniezzo, Colorni and Dorigo (1994) [75] applied exactly the same algorithm as AS using the QAP-specific min-max heuristic to compute the η values used in Equation 3. The resulting algorithm, AS-QAP, was tested on a set of standard problems and resulted to be of the same quality as meta-heuristic approaches like simulated annealing and evolutionary computation. More recently, Maniezzo and Colorni [74] and Maniezzo [73] developed two variants of AS-QAP and added to them a local optimizer. The resulting algorithms were compared with some of the best heuristics available for the QAP with very good results: their versions of AS-QAP gave the best results on all the tested problems.

Similar results were obtained by Stützle and Hoos (1998) with their *MMAS-QAP* algorithm [94] (*MMAS-QAP* is a straightforward application of *MMAS*, see Section 3.1.1.2, to the QAP), and by Gambardella, Taillard and Dorigo (1997) with their *HAS-QAP*.¹¹ *MMAS-QAP* and *HAS-QAP* were compared with some of the best heuristics available for the QAP on two classes of QAP problems: random and structured QAPs, where structured QAPs are instances of problems taken from real world applications. These ant algorithms were found to be the best performing on structured problems [52].

3.1.3 Job-shop scheduling problem

Colorni, Dorigo and Maniezzo (1994) [20] applied AS to the job-shop scheduling problem (JSP), which is formulated as follows. Given a set M of machines and a set J of jobs consisting of an ordered sequence of operations to be executed on these machines, the job-shop scheduling problem is the problem of assigning operations to machines and time intervals so that the maximum of the completion times of all operations is minimized and no two jobs are processed at the same time on the same machine. JSP is *NP*-hard [53]. The basic algorithm they applied was exactly the same as AS, where the η heuristic value was computed using the longest remaining processing time heuristic. Due to the different nature of the constraints with respect to the TSP they also defined a new way of building the ant's tabu list. AS-JSP was applied to problems of dimensions up to 15 machines and 15 jobs always finding solutions within 10% of the optimal value [20, 40]. These results, although not exceptional, are encouraging and suggest that further work could lead to a workable system. Also, a comparison with other approaches is necessary.

3.1.4 Vehicle routing problem

There are many types of vehicle routing problems (VRPs). Bullnheimer, Hartl and Strauss [11, 13, 15] applied an AS-like algorithm to the following instance. Let $G = (N, A, d)$ be

¹⁰ In fact, the TSP can be seen as the problem of assigning to each of n cities a different number chosen between 1 and n . QAP, as the TSP, is *NP*-hard [89].

¹¹ *HAS-QAP* is an ant algorithm which, although initially inspired by AS, does not strictly belong to the ACO meta-heuristic because of some peculiarities like ants which modify solutions as opposed to build them, and pheromone trail used to guide solutions modifications and not as an aid to direct their construction.

a complete weighted directed graph, where $N = (n_0, \dots, n_n)$ is the set of nodes, $A = \{(i, j) : i \neq j\}$ is the set of arcs, and each arc (i, j) has an associated weight $d_{ij} \geq 0$ which represents the distance between n_i and n_j . Node n_0 represents a depot, where M vehicles are located, each one of capacity D , while the other nodes represent customers locations. A demand $d_i \geq 0$ and a service time $\delta_i \geq 0$ are associated to each customer n_i ($d_0 = 0$ and $\delta_0 = 0$). The objective is to find minimum cost vehicle routes such that (i) every customer is visited exactly once by exactly one vehicle, (ii) for every vehicle the total demand does not exceed the vehicle capacity D , (iii) the total tour length of each vehicle does not exceed a bound L , and (iv) every vehicle starts and ends its tour in the depot.¹² AS-VRP, the algorithm defined by Bullnheimer, Hartl and Strauss for the above problem, is a direct extension of AS based on their AS_{rank} algorithm discussed in Section 3.1.1.2. They used various standard heuristics for the VRP [18, 79], and added a simple local optimizer based on the 2-opt heuristic [24]. They also adapted the way the tabu list is built by taking in consideration the constraints on the maximum total tour length L of a vehicle and its maximum capacity D . Comparisons on a set of standard problems showed that AS-VRP performance is at least interesting: it outperforms simulated annealing and neural networks, while it has a slightly lower performance than tabu search.

Gambardella, Taillard and Agazzi (1999) [51] have also attacked the VRP by means of an ACO algorithm. They first reformulate the problem by adding to the city set $M - 1$ depots, where M is the number of vehicles. Using this formulation, the VRP problem becomes a TSP with additional constraints. Therefore they can define an algorithm, called HAS-VRP, which is inspired by ACS: Each ant builds a complete tour without violating vehicle capacity constraints (each vehicle has associated a maximum transportable weight). A complete tour comprises many subtours connecting depots, and each sub-tour corresponds to the tour associated to one of the vehicles. Pheromone trail updates are done offline as in ACS. Also, a local optimization procedure based on edge exchanges is applied by the daemon. Results obtained with this approach are competitive with those of the best known algorithms and new upper bounds have been computed for well known problem instances. They also study the vehicle routing problem with time windows (VRPTW), which extends the VRP by introducing a time window $[b_i, e_i]$ within which a customer i must be served. Therefore, a vehicle visiting customer i before time b_i will have to wait. In the literature the VRPTW is solved considering two objectives functions: the first one is to minimize the number of vehicles and the second one is to minimize the total travel time. A solution with a lower number of vehicles is always preferred to a solution with a higher number of vehicles but lower travel time. In order to optimize both objectives simultaneously, a two-colony ant algorithm has been designed. The first colony tries to minimize the number of vehicles, while the other one uses V vehicles, where V is the number of vehicles computed by the first colony, to minimize travel time. The two colonies work using different sets of pheromone trails, but the best ants are allowed to update the pheromone trails of the other colony. This approach has been proved to be competitive with the best known methods in literature.

3.1.5 Shortest common supersequence problem

Given a set L of strings over an alphabet Σ , find a string of minimal length that is a supersequence of each string in L , where a string S is a supersequence of a string A if S can be obtained from A by inserting in A zero or more characters.¹³ This is the problem known as shortest common supersequence problem (SCS) that Michel and Middendorf (1998) [76] attacked by means of AS-SCS. AS-SCS differs from AS in that it

¹² Also in this case it can be easily seen that the VRP is closely related to the TSP: a VRP consists of the solution of many TSPs with common start and end cities. As such, VRP is an *NP*-hard problem.

¹³ Consider for example the set $L = \{bcab, bccb, baab, acca\}$. The string *baccab* is a shortest supersequence. The shortest common supersequence (SCS) problem is *NP*-hard even for an alphabet of cardinality two [81].

uses a *lookahead function* which takes into account the influence of the choice of the next symbol to append at the next iteration. The value returned by the lookahead function takes the place of the heuristic value η in the probabilistic decision rule (Equation 3). Also, in AS-SCS the value returned by a simple heuristic called LM [7] is factorized in the pheromone trail term. Michel and Middendorf further improved their algorithm by the use of an island model of computation (that is, different colonies of ants work on the same problem concurrently using private pheromone trail distributions; every fixed number of iterations they exchange the best solution found).

AS-SCS-LM (i.e., AS-SCS with LM heuristic, lookahead, and island model of computation) was compared in [76] with the MM [45] and LM heuristics, as well as with a recently proposed genetic algorithm specialized for the SCS problem. On the great majority of the test problems AS-SCS-LM resulted to be the best performing algorithm.

3.1.6 Graph coloring problem

Costa and Hertz (1997) [22] have proposed the AS-ATP algorithm for assignment type problems.¹⁴ The AS-ATP algorithm they define is basically the same as AS except that ants need to make two choices: first they choose an item, then they choose a resource to assign to the previously chosen item. These two choices are made by means of two probabilistic rules function of two distinct pheromone trails τ_1 and τ_2 and of two appropriate heuristic values η_1 and η_2 . In fact, the use of two pheromone trails is the main novelty introduced by AS-ATP. They exemplify their approach by means of an application to the graph coloring problem (GCP). Given a graph $G = (N, E)$, a q -coloring of G is a mapping $c : N \rightarrow \{1, \dots, q\}$ such that $c(i) \neq c(j)$ if $(i, j) \in E$. The GCP is the problem of finding a coloring of the graph G so that the number q of colors used is minimum. The algorithm they propose, called ANTCOL, makes use of well-known graph coloring heuristics like *recursive large first* (RLF) [70] and DSATUR [8]. Costa and Hertz tested ANTCOL on a set of random graphs and compared it with some of the best available heuristics. Results have shown that ANTCOL performance is comparable to that obtained by the other heuristics: on 20 randomly generated graphs of 100 nodes with any two nodes connected with probability 0.5 the average number of colors used by ANTCOL was 15.05, whereas the best known result [23, 43] is 14.95. More research will be necessary to establish whether the proposed use of two pheromone trails can be a useful addition to ACO algorithms.

3.1.7 Sequential ordering problem

The sequential ordering problem (SOP) [41] consists of finding a minimum weight Hamiltonian path on a directed graph with weights on the arcs and on the nodes, subject to precedence constraints among nodes. It is very similar to an asymmetric TSP in which the end city is not directly connected to the start city. The SOP, which is *NP*-hard, models real-world problems like single-vehicle routing problems with pick-up and delivery constraints, production planning, and transportation problems in flexible manufacturing systems and is therefore an important problem from an applications point of view.

Gambardella and Dorigo (1997) [50] attacked the SOP by HAS-SOP, an extension of ACS. In fact, HAS-SOP is the same as ACS except for the set of feasible nodes, which is built taking in consideration the additional precedence constraints, and for the local optimizer, which was a specifically designed variant of the well-known 3-opt procedure. Results obtained with HAS-SOP are excellent. Tests were run on a great number of standard problems¹⁵ and comparisons were done with the best available heuristic methods.

¹⁴ Examples of assignment type problems are the QAP, the TSP, graph coloring, set covering, and so on.

¹⁵ In fact, on all the problems registered in the TSPLIB, a well-known repository for TSP related benchmark problems available on the Internet at:

<http://www.iwr.uni-heidelberg.de/iwr/comopt/soft/TSPLIB95/TSPLIB.html>.

In all cases HAS-SOP was the best performing method in terms of solution quality and of computing time. Also, on the set of problems tested it improved many of the best known results.

3.2 Applications of ACO algorithms to dynamic combinatorial optimization problems

Research on the applications of ACO algorithms to dynamic combinatorial optimization problems has focused on communications networks. This is mainly due to the fact that network optimization problems have characteristics like inherent information and computation distribution, non-stationary stochastic dynamics, and asynchronous evolution of the network status, that well match those of the ACO meta-heuristic. In particular, the ACO approach has been applied to routing problems.

Routing is one of the most critical components of network control, and concerns the network-wide distributed activity of building and using *routing tables* to direct data traffic. The routing table of a generic node i is a data structure that says to data packets entering node i which should be the next node to move to among the set \mathcal{N}_i of neighbors of i . In the applications presented in this section routing tables for data packets are obtained by some functional transformation of ant-decision tables.

Let $G = (N, A)$ be a directed weighted graph, where each node in the set N represents a network node with processing/queuing and forwarding capabilities, and each oriented arc in A is a transmission system (link) with an associated weight defined by its physical properties. Network applications generate data flows from source to destination nodes. For each node in the network, the local routing component uses the local routing table to choose the best outgoing link to direct incoming data towards their destination nodes.

The generic routing problem can be informally stated as the problem to build routing tables so that some measure of network performance is maximized.¹⁶

Most of the ACO implementations for routing problems well match the general guidelines of the meta-heuristic shown in Figure 3. Ants are launched from each network node towards heuristically selected destination nodes (launching follows some random or problem-specific schedule). Ants, like data packets, travel across the network and build paths from source to destination nodes by applying a probabilistic transition rule that makes use of information maintained in pheromone trail variables associated to links and, in some cases, of additional local information. Algorithm-specific heuristics and information structures are used to score the discovered paths and to set the amount of pheromone ants deposit.

A common characteristic of ACO algorithms for routing is that the role of the daemon (line 6 of the ACO meta-heuristic of Figure 3) is much reduced: in the majority of the implementations it simply does not perform any actions.

ACO implementations for communications networks are grouped in two classes, those for connection-oriented and those for connection-less networks. In connection-oriented networks all the packets of a same session follow a common path selected by a preliminary setup phase. On the contrary, in connection-less, or datagram, networks data packets of a same session can follow different paths. At each intermediate node along the route from the source to the destination node a packet-specific forwarding decision is taken by the local routing component. In both types of networks best-effort routing, that is routing without any explicit network resource reservation, can be delivered. Moreover, in connection-oriented networks an explicit reservation (software or hardware) of the resources can be

¹⁶ The choice of what particular measure of network performance to use depends on the type of network considered and on which aspects of the provided services are most interesting. For example, in a telephone network performance can be measured by the percentage of accepted calls and by the mean waiting time to setup or refuse a call, while, in a Internet-like network, performance can be scored by the amount of correctly delivered bits per time unit (throughput), and by the distribution of data packet delays.

done. In this way, services requiring specific characteristics (in terms of bandwidth, delay, and so on) can be delivered.¹⁷

3.2.1 Connection-oriented networks routing

The work by Schoonderwoerd, Holland, Bruten and Rothkrantz (1996) [86, 87] has been, to our knowledge, the first attempt to apply an ACO algorithm to a routing problem. Their algorithm, called ant-based control (ABC), was applied to a model of the British Telecom (BT) telephone network. The network is modeled by a graph $G = (N, A)$, where each node i has the same functionalities as a crossbar switch with limited connectivity (capacity) and links have infinite capacity (that is, they can carry a potentially infinite number of connections). Each node i has a set \mathcal{N}_i of neighbors, and is characterized by a total capacity C_i , and a spare capacity S_i . C_i represents the maximum number of connections node i can establish, while S_i represents the percentage of capacity which is still available for new connections. Each link (i, j) connecting node i to node j has an associated vector of pheromone trail values τ_{ijd} , $d = 1, \dots, i-1, i+1, \dots, n$. The value τ_{ijd} represents a measure of the desirability of choosing link (i, j) when the destination node is d .

Because the algorithm does not make use of any additional local heuristics, only pheromone values are used to define the ant-decision table values: $a_{ind}(t) = \tau_{ind}(t)$. The ant stochastic decision policy uses the pheromone values as follows: $\tau_{ind}(t)$ gives the probability that a given ant, the destination of which is node d , be routed at time t from node i to neighbor node n . An exploration mechanism is added to the ant's decision policy: with some low probability ants can choose the neighbor to move to following a uniformly random scheme over all the current neighbors. The ant internal state keeps trace only of the ant source node and launching time. No memory about the visited nodes is maintained to avoid ant cycles. Routing tables for calls are obtained using ant-decision tables in a deterministic way: at setup time a route from node s to node d is built by choosing sequentially and deterministically, starting from node s , the neighbor node with the highest probability value until node d is reached. Once the call is set up in this way, the spare capacity S_i of each node i on the selected route is decreased by a fixed amount. If at call set up time any of the nodes along the route under construction has no spare capacity left, then the call is rejected. When a call terminates, the corresponding reserved capacity of nodes on its route is made available again for other calls. Ants are launched at regular temporal intervals from all the nodes towards destination nodes selected in a uniform random way. Ants deposit pheromone only online, step-by-step, on the links they visit (they do not deposit pheromone after the path has been built, that is, they do not implement the procedure of lines 30-34 of the ACO meta-heuristic of Figure 3). An ant k originated in node s and arriving at time t in node j from node i adds an amount $\Delta\tau^k(t)$ of pheromone to the value $\tau_{jis}(t)$ stored on link (j, i) . The updated value $\tau_{jis}(t)$, that represents the desirability to go from node j to destination node s via node i , will be used by ants moving in the opposite direction of the updating ant. This updating strategy can be applied when the network is (approximately) cost-symmetric, that is, when it is reasonable to use an estimate of the cost from node i to node j as an estimate of the cost from node j to node i . In the network model used by Schoonderwoerd et al. cost-symmetry is a direct consequence of the assumptions made on the switches and transmission link structure. The pheromone trail update formula is:

$$\tau_{jis}(t) \leftarrow \tau_{jis}(t) + \Delta\tau^k(t) \quad (13)$$

After the visited entry has been updated, the pheromone value of all the entries relative to the destination s decays. Pheromone decay, as usual, corresponds to the evaporation

¹⁷ For example, telephone calls need connection-oriented networks able to guarantee the necessary bandwidth during all the call time.

of real pheromone.¹⁸ In this case the decay factor is set to $1/(1 + \Delta\tau^k(t))$ so that it operates a normalization of the pheromone values which continue therefore to be usable as probabilities:

$$\tau_{ins}(t) \leftarrow \frac{\tau_{ins}(t)}{(1 + \Delta\tau^k(t))}, \quad \forall n \in \mathcal{N}_i \quad (14)$$

The value $\Delta\tau^k(t)$ is a function of the ant age. Ants move over a control network isomorphic to the real one. They grow older after each node hop and they are virtually delayed in nodes as a function of the node spare capacity. By this simple mechanism, the amount of pheromone deposited by an ant is made inversely proportional to the length and to the degree of congestion of the selected path. Therefore, the overall effect of ants on pheromone trail values is such that routes which are visited frequently and by “young” ants will be favored when building paths to route new calls.

In ABC no daemon actions are included into the algorithm. Each new call is accepted or rejected on the basis of a setup packet that looks for a path with spare capacity by probing the deterministically best path as indicated by the routing tables.

ABC has been tested on the above-described model of the British Telecom (BT) telephone network (30 nodes) using a sequential discrete time simulator and compared, in terms of percentage of accepted calls, to an agent-based algorithm developed by BT researchers. Results were encouraging¹⁹: ABC always performed significantly better than its competitor on a variety of different traffic situations.

White, Pagurek and Oppacher (1998) [100] use an ACO algorithm for routing in connection-oriented point-to-point and point-to-multipoint networks. The algorithm follows a scheme very similar to AS (see Section 3.1.1.1): the ant-decision table has the same form as AS’s (Eq. 2) and the decision rule (Eq. 3) is identical. The heuristic information η is locally estimated by link costs. From the source node of each incoming connection, a group of ants is launched to search for a path. At the beginning of the trip each ant k sets a private path cost variable C_k to 0, and after each link crossing the path cost is incremented by the link cost l_{ij} : $C_k \leftarrow C_k + l_{ij}$. When arrived at destination, ants move backward to their source node and at each node they use a simple additive rule to deposit pheromone on the visited links. The amount of deposited pheromone is a function of the whole cost C_k of the path, and only this online step-by-step updating is used to update pheromone. When all the spooled ants arrive back at the source node, a simple local daemon algorithm decides whether to allocate a path, based on the percentage of ants that followed a same path. Moreover, during all the connection lifetime, the local daemon launches and coordinates exploring ants to re-route the connection paths in case of network congestion or failures. A genetic algorithm [57, 64] is used online to evolve the parameters α and β of the transition rule formula, which determine the relative weight of pheromone and link costs (because of this mechanism the algorithm is called ASGA, ant system plus genetic algorithm). Some preliminary results were obtained testing the algorithm on several networks and using several link cost functions. Results are promising: the algorithm is able to compute shortest paths and the genetic adaptation of the rule parameters considerably improves the algorithm’s performance.

Bonabeau, Henaux, Guérin, Snyers, Kuntz and Théraulaz (1998) [6] improved the ABC algorithm by the introduction of a dynamic programming mechanism. They update the pheromone trail values of all the links on an ant path not only with respect to the ant’s origin node, but also with respect to all the intermediate nodes on the sub-path between the origin and the ant current node.

¹⁸ Schoonderwoerd et al. developed ABC independently from previous ant colony optimization work. Therefore, they do not explicitly speak of pheromone evaporation, even if their probability re-normalization mechanism plays the same role.

¹⁹ In the following we use the word “encouraging” whenever interesting results were obtained but the algorithm was compared only on simple problems, or with no state-of-the-art algorithms or under limited experimental conditions.

Di Caro and Dorigo (1998) [31] are currently investigating the use of AntNet-FS to manage fair-share best-effort routing in high-speed connection-oriented networks. AntNet-FS is a derivation of AntNet, an algorithm for best-effort routing in connection-less networks the same authors developed. Therefore, we postpone the description of AntNet-FS to the next sub-subsection, where AntNet and its extensions are described in detail.

3.2.2 Connection-less networks routing

Several ACO algorithms have been developed for routing on connection-less networks taking inspiration both from AS (Sec. 3.1.1.1) in general and from ABC (Sec. 3.2.1) in particular.

Di Caro and Dorigo (1997) [26, 27, 28, 29, 30] developed several versions of AntNet, an ACO algorithm for distributed adaptive routing in best-effort connection-less (Internet-like) data networks. The main differences between ABC and AntNet are that (i) in AntNet real trip times experienced by ants (ants move over the same, real network as data packets) and local statistical models are used to evaluate paths goodness, (ii) pheromone is deposited once a complete path is built (this is a choice dictated by a more general assumption of cost asymmetry made on the network), and (iii) the ant decision rule makes use of local heuristic information η about the current traffic status.

In AntNet the ant-decision table $\mathcal{A}_i = [a_{ind}(t)]_{|\mathcal{N}_i|, |N|-1}$ of node i is obtained by the composition of the local pheromone trail values with the local heuristic values as follows:

$$a_{ind}(t) = \frac{\omega \tau_{ind}(t) + (1 - \omega) \eta_n}{\omega + (1 - \omega)(|\mathcal{N}_i| - 1)} \quad (15)$$

where \mathcal{N}_i is the set of neighbors of node i , $n \in \mathcal{N}_i$, d is the destination node, η_n is a $[0,1]$ -normalized heuristic value inversely proportional to the length of the local link queue towards neighbor n , $\omega \in [0,1]$ is a weighting factor and the denominator is a normalization term. The decision rule of the ant located at node i and directed towards destination node d (at time t) uses the entry $a_{ind}(t)$ of the ant-decision table as follows: $a_{ind}(t)$ is simply the probability of choosing neighbor n . This probabilistic selection is applied over all the not yet visited neighbors by the ant, or over all the neighbors in case all the neighbors have already been visited by the ant. While building the path to the destination, ants move using the same link queues as data. In this way ants experience the same delays as data packets and the time T_{sd} elapsed while moving from the source node s to the destination node d can be used as a measure of the path quality. The overall “goodness” of a path is evaluated by an heuristic function of the trip time T_{sd} and of local adaptive statistical models. In fact, paths need to be evaluated relative to the network status because a trip time T judged of low quality under low congestion conditions could be an excellent one under high traffic load. Once a path has been completed ants deposit on the visited nodes an amount of pheromone proportional to the goodness of the path they built. AntNet’s ants use only this online delayed way to update pheromone, differently from ABC which uses only the online step-by-step strategy (lines 30-34 and 24-27 respectively of the ACO meta-heuristic of Figure 3). To this purpose, after reaching their destination nodes, ants move back to their source nodes along the same path but backward and using high priority queues, to allow a fast propagation of the collected information (in AntNet the term “forward ant” is used for ants moving from source to destination nodes, and the term “backward ant” for ants going back to their source nodes). During the backward path, the pheromone value of each visited link is updated with a rule similar to ABC’s. AntNet differs from ABC also in a number of minor details, the most important of which are: (i) ants are launched from each node towards destinations chosen to probabilistically match the traffic patterns, (ii) all the pheromone values on an ant path are updated with respect to all the successor nodes of the (forward) path (as it

is done also in [6]), (iii) cycles are removed online from the ant’s paths²⁰, and (iv) data packets are routed probabilistically using routing tables obtained by means of a simple functional transformation of the ant-decision tables. AntNet was tested using a continuous time discrete event network simulator, on a wide variety of different spatial and temporal traffic conditions, and on several real and randomly generated network configurations (ranging from 8 to 150 nodes). State-of-the-art static and adaptive routing algorithms have been used for comparison. Results were excellent: AntNet showed striking superior performance in terms of both throughput and packet delays. Moreover, it appears to be very robust to the ant production rate and its impact on network resources is almost negligible.

Di Caro and Dorigo (1998) [31, 32] recently developed an enhanced version of AntNet, called AntNet-FA.²¹ AntNet-FA is the same as AntNet except for the following two aspects. First, forward ants are substituted by so-called “flying ants”: while building a path from source to destination node, flying ants make use of high priority queues and do not store the trip times T . Second, each node maintains a simple local model of the local link queue depletion process. By using this model, rough estimates of the missing forward ant trip times are built. Backward ants read online these estimates and use them to evaluate the path quality and consequently to compute the amount of pheromone to deposit. AntNet-FA appears to be more reactive, the information collected by ants is more up-to-date and is propagated faster than in the original AntNet. AntNet-FA has been observed to perform much better than the original AntNet in best-effort connection-less networks [32].

Starting from AntNet-FA Di Caro and Dorigo (1998) [31] are currently developing AntNet-FS, a routing and flow control system to manage multi-path adaptive fair-share routing in connection-oriented high-speed networks. In AntNet-FS, some ants have some extra functionalities to support the search and allocation of multi-paths for each new incoming user session. Forward setup ants fork to search for convenient multi-paths (virtual circuits) to allocate the session. A daemon component local to the session end-points decides to accept or not the virtual circuits discovered by the forward setup ants. Accepted virtual circuits are allocated by the backward setup ants, reserving at the same time the session’s bandwidth in a fair-share [72] fashion over the circuit nodes. The allocated bandwidth is dynamically redistributed and adapted after the arrival of a new session or the departure of an old one. The AntNet-FS approach looks very promising for high-speed networks (like ATM), but needs more testing.

Subramanian, Druschel and Chen (1997) [95] proposed the *regular ants* algorithms, which essentially is an application of Schoonderwoerd’s et al. ABC algorithm [86, 87] to packet switched networks, where the only difference is the use of links costs instead of ants age. The way their ants use links costs requires the network to be (approximately) cost-symmetric. They also propose *uniform ants*, that is, ants without a precise destination, which live for a fixed amount of time in the network and explore it by using a uniform probability scheme over the node neighbors. Uniform ants do not use the autocatalytic mechanism that characterizes all ACO algorithms and therefore do not belong to the ACO meta-heuristic.

Heusse, Snyers, Guérin and Kuntz (1998) [62] developed a new algorithm for general cost-asymmetric networks, called Co-operative Asymmetric Forward (CAF). In CAF, each data packet, after going from node i to node j , releases on node j the information c_{ij} about the sum of the experienced waiting and crossing times from node i . This information is used as an estimate of the time distance to go from i to j , and is read by the ants traveling in the opposite direction to perform online step-by-step pheromone updating (no online delayed pheromone updating is used in this case). The algorithm’s authors tested CAF

²⁰ This is a simple form of backtracking.

²¹ In the original paper [32] the same algorithm was called AntNet-CO, because the algorithm was developed in the perspective of connection-oriented routing, while here and in the future the authors choose to use the name AntNet-FA, to emphasize the “flying ant” nature of forward ants.

under some static and dynamic conditions, using the average number of packets waiting in the queues and the average packet delay as performance measures. They compared CAF to an algorithm very similar to an earlier version of AntNet. Results were encouraging, under all the test situations CAF performed better than its competitors.

Van der Put and Rothkrantz (1998) [97, 98] designed ABC-backward, an extension of the ABC algorithm applicable to cost-asymmetric networks. They use the same forward-backward ant mechanism as in AntNet: Forward ants, while moving from the source to the destination node, collect information on the status of the network, and backward ants use this information to update the pheromone trails of the visited links during their journey back from the destination to the source node. In ABC-backward, backward ants update the pheromone trails using an updating formula identical to that used in ABC, except for the fact that the ants' age is replaced by the trip times experienced by the ants in their forward journey. Van der Put and Rothkrantz have shown experimentally that ABC-backward has a better performance than ABC on both cost-symmetric, because backward ants can avoid depositing pheromone on cycles, and cost-asymmetric networks. They apply ABC-backward to a fax distribution problem proposed by the Dutch largest telephone company (KPN Telecom).

3.3 Parallel implementations

The very nature of ACO algorithms lends them to be naturally parallelized in the data or population domains. In particular, many parallel models used in other population-based algorithms can be easily adapted to the ACO structure (e.g., migration and diffusion models adopted in the field of parallel genetic algorithms, see for example reviews in [16, 38]).

Early experiments with parallel versions of AS for the TSP on the Connection Machine CM-2 [63] adopted the approach of attributing a single processing unit to each ant [4]. Experimental results showed that communication overhead can be a major problem with this approach on fine grained parallel machines, since ants end up spending most of their time communicating to other ants the modifications they did to pheromone trails. In fact, the algorithm's behavior was not impressive and scaled up very badly when increasing the problem dimensions. Better results were obtained on a coarse grained parallel network of 16 transputers [4, 34]. The idea here was to divide the colony in p subcolonies, where p is the number of available processors. Each subcolony acts as a complete colony and implements therefore a standard AS algorithm. After each subcolony has completed an iteration of the algorithm, a hierarchical broadcast communication process collects the information about the tours of all the ants in all the subcolonies and then broadcasts this information to all the p processors so that a concurrent update of the pheromone trails can be done. In this case the speed-up was nearly linear when increasing the number of processors and this behavior did not change significantly for increasing problem dimensions.

More recently, Bullnheimer, Kotsis and Strauss [14] proposed two coarse grained parallel versions of AS. The first one, called Synchronous Parallel Implementation (SPI), is basically the same as the one implemented by Bolondi and Bondanza [4], while the second one, called Partially Asynchronous Parallel Implementation (PAPI), exchanges pheromone information among subcolonies every fixed number of iterations done by each subcolony. The two algorithms have been evaluated by simulation. The findings show that the reduced communication due to the less frequent exchange of pheromone trail information among subcolonies determines a better performance of the PAPI approach with respect to running time and speedup. More experimentation is necessary to compare the quality of the results produced by the SPI and the PAPI implementations.

Krüger, Merkle and Middendorf [68] investigated which (pheromone trail) information should be exchanged between the m subcolonies and how this information should be used to update the subcolony's trail information. They compared an exchange of (i) the

global best solution (every subcolony uses the global best solution to choose where to add pheromone trail), (ii) the local best solutions (every subcolony receives the local best solution from all other subcolonies and updates pheromone trail on the corresponding arcs), and (iii) the total trail information (every colony computes the average over the trail information of all colonies); that is, if $\tau^l = [\tau_{ij}^l]$ is the trail information of subcolony l , $1 \leq l \leq m$ then every colony l sends τ^l to the other colonies and afterwards computes $\tau_{ij}^l = \sum_{h=1}^m \tau_{ij}^h$, $1 \leq i, j \leq n$. The results indicate that methods (i) and (ii) are faster and give better solutions than method (iii). But further investigations are necessary.

Last, Stützle [91] presents computational results for the execution of parallel independent runs on up to ten processors of his \mathcal{MMAS} algorithm [92, 93]. The execution of parallel independent runs is the easiest way to obtain a parallel algorithm and, obviously, it is a reasonable approach only if the underlying algorithm, as it is the case with ACO algorithms, is randomized. Stützle’s results show that the performance of \mathcal{MMAS} grows with the number of processors.

4 Related work

ACO algorithms show similarities with some optimization, learning and simulation approaches like heuristic graph search, Monte Carlo simulation, neural networks, and evolutionary computation. These similarities are briefly discussed in the following.

Heuristic graph search. In ACO algorithms each ant performs an heuristic graph search in the space of the components of a solution: ants take biased probabilistic decisions to choose the next component to move to, where the bias is given by an heuristic evaluation function which favors components which are perceived as more promising. It is interesting to note that this is different from what happens, for example, in *stochastic hillclimbers* [78] or in *simulated annealing* [66], where (i) an acceptance criteria is defined and only those randomly generated moves which satisfy the criteria are executed, and (ii) the search is usually performed in the space of the solutions.

Monte Carlo simulation. ACO algorithms can be interpreted as parallel replicated Monte Carlo systems [90]. Monte Carlo systems [84] are general stochastic simulation systems, that is, techniques performing repeated sampling experiments on the model of the system under consideration by making use of a stochastic component in the state sampling and/or transition rules. Experiment results are used to update some statistical knowledge about the problem, as well as the estimate of the variables the researcher is interested in. In turn, this knowledge can be also iteratively used to reduce the variance in the estimation of the desired variables, directing the simulation process towards the most interesting state space regions. Analogously, in ACO algorithms the ants sample the problem’s solution space by repeatedly applying a stochastic decision policy until a feasible solution of the considered problem is built. The sampling is realized concurrently by a collection of differently instantiated replicas of the same ant type. Each ant “experiment” allows to adaptively modify the local statistical knowledge on the problem structure (i.e., the pheromone trails). The recursive transmission of such knowledge by means of stigmergy determines a reduction in the variance of the whole search process: the so far most interesting explored transitions probabilistically bias future search, preventing ants to waste resources in not promising regions of the search space.

Neural networks. Ant colonies, being composed of numerous concurrently and locally interacting units, can be seen as “connectionist” systems [42], the most famous examples of which are neural networks [3, 61, 85]. From a structural point of view, the parallel between the ACO meta-heuristic and a generic neural network is obtained by putting each state i visited by ants in correspondence with a neuron i , and the problem-specific neighborhood structure of state i in correspondence with the set of synaptic-like links exiting neuron i . The ants themselves can be seen as input signals concurrently

propagating through the neural network and modifying the strength of the synaptic-like inter-neuron connections. Signals (ants) are locally propagated by means of a stochastic transfer function and the more a synapse is used, the more the connection between its two end-neurons is reinforced. The ACO-synaptic learning rule can be interpreted as an a posteriori rule: signals related to good examples, that is, ants which discovered a good quality solution, reinforce the synaptic connections they traverse more than signals related to poor examples. It is interesting to note that the ACO-neural network algorithm does not correspond to any existing neural network model.

The ACO-neural network is also reminiscent of networks solving *reinforcement learning* problems [96]. In reinforcement learning the only feedback available to the learner is a numeric signal (the *reinforcement*) which scores the result of actions. This is also the case in the ACO meta-heuristic: The signals (ants) fed into the network can be seen as input examples with associated an approximate score measure. The strength of pheromone updates and the level of stochasticity in signal propagation play the role of a learning rate, controlling the balance between exploration and exploitation.

Finally, it is worth to make a reference to the work of Chen [17], who proposed a neural network approach to TSP which bears important similarities with the ACO approach. Like in ACO algorithms, Chen builds a tour in an incremental way, according to synaptic strengths. It makes also use of candidate lists and 2-opt local optimization. The strengths of the synapses of the current tour and of all previous tours are updated according to a Boltzmann-like rule and a learning rate playing the role of an evaporation coefficient. Although there are some differences, the common features are, in this case, striking.

Evolutionary computation. There are some general similarities between the ACO meta-heuristic and evolutionary computation (EC) [44]. Both approaches use a population of individuals which represent problem solutions, and in both approaches the knowledge about the problem collected by the population is used to stochastically generate a new population of individuals. A main difference is that in EC algorithms all the knowledge about the problem is contained in the current population, while in ACO a memory of past performance is maintained under the form of pheromone trails.

An EC algorithm which is very similar to ACO algorithms in general and with AS in particular is Baluja and Caruana's *Population Based Incremental Learning (PBIL)* [1]. PBIL maintains a vector of real numbers, the generating vector, which plays a role similar to that of the population in genetic algorithms [64, 57]. Starting from this vector, a population of binary strings is randomly generated: each string in the population will have the i -th bit set to 1 with a probability which is a function of the i -th value in the generating vector. Once a population of solutions is created, the generated solutions are evaluated and this evaluation is used to increase (or decrease) the probabilities of each separate component in the generating vector so that good (bad) solutions in the future generations will be produced with higher (lower) probability. It is clear that in ACO algorithms the pheromone trail values play a role similar to Baluja and Caruana's generating vector, and pheromone updating has the same goal as updating the probabilities in the generating vector. A main difference between ACO algorithms and PBIL consists in the fact that in PBIL all the probability vector components are evaluated independently, making the approach working well only in the cases the solution is separable in its components.

The $(1, \lambda)$ *evolution strategy* is another EC algorithm which is related to ACO algorithms, and in particular to ACS. In fact, in the $(1, \lambda)$ *evolution strategy* the following steps are iteratively repeated: (i) a population of λ solutions (ants) is initially generated, then (ii) the best individual of the population is saved for the next generation, while all the other solutions are discarded, and (iii) starting from the best individual, $\lambda - 1$ new solutions are stochastically generated by mutation, and finally (iv) the process is iterated going back to step (ii). The similitude with ACS is striking.

Stochastic learning automata. This is one of the oldest approaches to machine learning (see [77] for a review). An automaton is defined by a set of possible actions and

a vector of associated probabilities, a continuous set of inputs and a learning algorithm to learn input-output associations. Automata are connected in a feedback configuration with the environment, and a set of penalty signals from the environment to the actions is defined. The similarity of stochastic learning automata and ACO approaches can be made clear as follows. The set of pheromone trails available on each arc/link is seen as a set of concurrent stochastic learning automata. Ants play the role of the environment signals, while the pheromone update rule is the automaton learning rule. The main difference lies in the fact that in ACO the “environment signals” (i.e., the ants) are stochastically biased, by means of their probabilistic transition rule, to direct the learning process towards the most interesting regions of the search space. That is, the whole environment plays a key, active role to learn good state-action pairs.

5 Discussion

The ACO meta-heuristic was defined *a posteriori*, that is, it is the result of a synthesis effort effectuated on a set of algorithms inspired by a common natural process. Such a synthesis can be very useful because (i) it is a first attempt to characterize this new class of algorithms, and (ii) it can be used as a reference to design new instances of ACO algorithms. On the other hand, the *a posteriori* character of the synthesis determines a great variety in the way some aspects of the meta-heuristic are implemented, as discussed in the following.

Role of the local heuristic. Most of the ACO algorithms presented combine pheromone trails with local heuristic values to obtain ant-decision tables. An exception are Schoonderwoerd et al. ABC algorithm and all the derived algorithms (ABC-smart ants, ABC-backward, regular ants, and CAF) in which ant-decision tables are obtained using only pheromone trail values. Current wisdom indicates that the use of a heuristic value, whenever possible, improves ACO performance considerably. The nature of the heuristic information differs between static and dynamic problems. In all static problems attacked by ACO a simple heuristic value directly obtainable from the problem definition was used. On the contrary, in dynamic problems the heuristic value must be estimated by local statistical sampling of the dynamic system.

Step-by-step versus delayed online solution evaluation. In dynamic combinatorial optimization problems some of the proposed ACO algorithms use step-by-step online solution evaluation: ABC, ABC-smart, and regular ants, that take advantage of the cost-symmetric nature of the network model, and CAF, that, although applied to a cost-asymmetric network, can apply step-by-step solution evaluation by exploiting information deposited on nodes by data packet traveling in the opposite direction of ants. The other algorithms applied to cost-asymmetric networks, AntNet and ABC-backward, use delayed online solution evaluation. For the static optimization problems considered the use of step-by-step online solution evaluation would be misleading because problem constraints make the quality of partial solutions not a good estimate of the quality of complete solutions.

Pheromone trail directionality. The pheromone trail can have directional properties. This is true for all dynamic optimization problems considered. Differently, in all the applications to static problems (3.1) pheromone trail is not directional: an ant using arc (i, j) will see the same pheromone trail values independent of the node it is coming from. (It is the decision policy that can take in consideration the node, or the series of nodes, the ant is coming from.)

Implicit solution evaluation. One of the interesting aspects of real ants shortest path finding behavior is that they exploit *implicit solution evaluation*: if an ant takes a shorter path it will arrive to the destination before any other ant that took a longer path. Therefore, shorter paths will receive pheromone earlier and they start to attract new ants

before longer paths. This implicit solution evaluation property is exploited by the ACO algorithms applied to routing, and not by those applied to static optimization problems. The reason for this is that implicit solution evaluation is obtained for free whenever the speed with which ants move on the problem representation is inversely proportional to the cost of each state transition during solution construction. While this is the most natural way to implement artificial ants for network applications, it is not an efficient choice for the considered static problems. In fact, in this case it would be necessary to implement an extra algorithm component to manage each ant's speed, which would require extra computation resources without any guarantee of improved performance.

6 Conclusions

In this paper we have introduced the ant colony optimization (ACO) meta-heuristic and we have given an overview of ACO algorithms. ACO is a novel and very promising research field situated at the crossing between artificial life and operations research. The ant colony optimization meta-heuristic belongs to the relatively new wave of stochastic meta-heuristics like evolutionary computation [44], simulated annealing [66], tabu search [55, 56], neural computation [3, 61, 85], and so on, which are built around some basic principles taken by the observation of a particular natural phenomenon. As it is very common in the practical usage of these heuristics, ACO algorithms take often some distance from their inspiring natural metaphor. Often ACO algorithms are enriched with capacities that do not find a counterpart in real ants, like local search and global-knowledge-based actions, so that they can compete with more application-specific approaches. ACO algorithms so enriched are very competitive and in some applications they have reached world-class performance. For example, on structured quadratic assignment problems AS-QAP, HAS-QAP, and \mathcal{M} MAS-QAP are currently the best available heuristics. Other very successful applications are those to the sequential ordering problem, for which HAS-SOP is by far the best available heuristic, and to data network routing, where AntNet resulted to be superior to a whole set of state-of-the-art algorithms.

Within the artificial life field, ant algorithms represent one of the most successful applications of swarm intelligence.²² One of the most characterizing aspect of swarm intelligent algorithms, shared by ACO algorithms, is the use of the stigmergetic model of communication. We have seen that this form of indirect distributed communication plays an important role in making ACO algorithms successful. There are however examples of applications of stigmergy based on social insects behaviors other than ants foraging behavior. For example, the stigmergy mediated allocation of work in ant colonies has inspired models of task allocation in a distributed mail retrieval system, dead body aggregation and brood sorting, again in ant colonies, have inspired a data clustering algorithm, and models of collective transport by ants have inspired transport control strategies for groups of robot.²³

In conclusion, we hope this paper has achieved its goal: To convince the reader that ACO, and more generally the stigmergetic model of communication, are worth further research.

²² Swarm intelligence can be defined as the field which covers “any attempt to design algorithms or distributed problem-solving devices inspired by the collective behavior of social insect colonies and other animal societies” ([5], page 7).

²³ These and other examples of the possible applications of stigmergetic systems are discussed in details by Bonabeau, Dorigo and Théraulaz in [5].

7 Acknowledgments

We are grateful to Nick Bradshaw, Bernd Bullnheimer, Martin Heusse, Owen Holland, Vittorio Maniezzo, Martin Middendorf, Ruud Schoonderwoerd, and Dominique Snyers for critical reading of a draft version of this article. We also wish to thank Eric Bonabeau and the two referees for their valuable comments. Marco Dorigo acknowledges support from the Belgian FNRS, of which he is a Research Associate. This work was supported by a Madame Curie Fellowship awarded to Gianni Di Caro (CEC-TMR Contract N. ERBFMBICT 961153).
